yesterday on April 11, just one week after releasing our cosmological BAO from galaxies and quasars and the Lyman-alpha forest.

imaging data

Yesterday's papers do not exhibit new results, but represent major steps towards the cosmology results from the RSD (aka Full Shape) analysis release soon. They fall into the two categories:

target selection
and survey
validation

- DESI 2024 II: Sample definitions, characteristics, and two-point clustering statistics.
- DESI 2024 V: Analysis of the full-shape of two-point clustering statistics for galaxies and quasars

theory and
simulations

other DESI science

DESI 2024 II: Sample definitions, characteristics, and two-point clustering statistics.

These papers describe the methods by which we ensure that all results take into account systematic effects, including: incomplete galaxy sampling, biases, and imaging systematics. For a general overview of how DESI selects targets, see [this blog post](#), and for more information about survey validation, see [this blog post](#).

Most papers attributed to this category are yet to come out. But one of them, the paper presenting the DESI Blinding strategy, was already released yesterday, given its synergy with the BAO papers released a week ago, and with the Full Shape

Summary:

instrument design

Short: This paper introduces the blinding strategy ensuring a data and confirmation bias, validating it using mock catalogs and blinded data.

imaging data

target selection
and survey
validation

Long: This paper introduces the galaxy and quasar BAO and RSD blinding where galaxy redshifts are displaced in two ways, such that overall the dark energy expansion history different than in the fiducial model with 1) a cosmological constant and 2) a different growth of structure history compared to a different law of gravity. Additionally, galaxy weights are applied to the effect of primordial non-Gaussianity. BAO fits and full-shape fits (Shaper) applied to one realization of Abacus mocks that was blinded according to different varying dark energy and primordial non-Gaussianity scenarios. Additionally, the blinding scheme was applied to the blinded data and that “double-blinded” catalog using BAO fits.

This figure shows for one particular case the fitted isotropic and anisotropic parameters scaled to the expectation obtained from 8 different values of (w_0, w_a) and either positive ($f_{\text{NL}}=20$) or negative ($f_{\text{NL}}=-20$) non-Gaussianity. Deviations from 1 are observed only for very extreme blinding values.

DESI 2024 V: Analysis of the full-shape of the point clustering statistics from galaxies and quasars

This set of papers document various clustering statistics, modeling, and systematic analysis of DESI's Year one galaxy and quasar samples. While there is yet more to come out, yesterday's set of papers focus on the comparison between different

full-shape of 2-point clustering statistics: instrument design

1. Template fits: Here, templates of the two-point statistics at a fixed cosmology are used to extract physical information from the data called ‘compressed parameters’ such as the isotropic and anisotropic scales, the growth rate, and the scale-dependence, or shape. The rather new observable proposed in the ‘ShapeFit’ method, which is the state-of-the-art method when it comes to template fits. Cosmological parameters are obtained by fitting cosmological models to these parameters measured in each redshift bin. This is very similar to the philosophy behind the BAO analysis, where the (compressed) BAO parameters are measured first in each redshift bin and cosmological parameters are obtained in a second step.
2. Full modeling fits: Here, the step of measuring compressed parameters is avoided. Instead, the 2-point statistics of all redshift bins are directly fitted according to the cosmological model. This is similar to the philosophy behind the analysis of cosmic microwave background (CMB) or weak lensing, where the 2-point statistics are also fitted directly, without an additional compression step in between.

Both these approaches have advantages and disadvantages. Template fits are designed to extract only the most robust information and allows for a modular interpretation. For example, they allow us to decouple the information on expansion history, growth history, and shape in an effective way. On the other hand, the extra compression step within the template fit method can erase some of the cosmological information within 2-point statistics. Direct fits allow us to

all DESI papers

Long: This paper demonstrates the level of consistency between the current effective field theory models used for fitting galaxy power spectra in redshift space. We show, by fitting to Abacus cubic mocks, that velocileptors (Lagrangian Eulerian PT versions), PyBird, and FOLPSv give consistent constraints on the ShapeFit parameters with differences in means of $<0.1\sigma$. We also compare noiseless theoretical data vectors created by each model while varying k_{max} and show that for $k_{\text{max}}=0.18 \text{ h/Mpc}$ the systematic errors are far below the statistical errors for all parameters at precisions corresponding to 8 (Gpc/h)^3 volumes.
